

METHOD AND DEVICE RESPONSIVE TO DIAPHRAGMATIC
ACTIVITY FOR ADJUSTING POSITIVE PRESSURE
ASSIST DURING EXPIRATION

5

FIELD OF THE INVENTION

The present invention relates to a method and device for controlling positive pressure assist to a patient during expiration in relation to the electrical activity of a respiration-related muscle of the patient during expiration.

10

More specifically, but not exclusively, the present invention relates to a method and device for adjusting, during mechanical ventilation of a patient, a ventilation feature selected, for example, from the group consisting of: Positive End-Expiratory Pressure (PEEP), Continuous Positive Airway Pressure (CPAP), Biphasic Positive Airway Pressure (BiPAP), and any other mode of mechanical ventilation that provides positive pressure assist to the patient during expiration.

15

BACKGROUND OF THE INVENTION

20

PEEP is a standard treatment for the care of patients undergoing mechanical ventilation. PEEP consists of applying a constant positive pressure to the patient's airways during expiration, with the aim of avoiding expiratory lung collapse. Application of PEEP is particularly important during mechanical ventilation of infants demonstrating lower than adequate End-Expiratory Lung Volumes (EELV). The combination of a highly compliant chest wall, and a small caliber of intrathoracic airways predispose infants to closure of the small airways, alveolar collapse at the end of expiration, and thus predispose to hypoxemia [Findley, L.J.; Ries, A.L.; Tisi, M.; Wagner, P.D.; "Hypoxemia During Apnea in Normal Subjects: Mechanisms and Impact of Lung Volume"; J. Appl. Physiol.; Dec 1983; 55(6); pp 1777-83].

25

30

Continuous Positive Airway Pressure (CPAP) is a continuous delivery of positive airway pressure to the patient during both inspiration and expiration, while Biphasic Positive Airway Pressure (BiPAP) is a biphasic delivery of positive airway pressure to the patient.

5 A variety of different interfaces (nasal prongs, face mask, or endotracheal tube, etc.) are currently used to deliver CPAP to a patient's airways via either continuous or variable gas flow ventilators. CPAP is sometimes also called Continuous Distending Pressure (CDP). The function of CPAP is to keep the patient's airways open.

10 BiPAP can be described as pressure-controlled ventilation in a system allowing unrestricted spontaneous breathing at any moment of the ventilatory cycle. It can also be described as a CPAP system with a time-cycled change of the level of applied CPAP. BiPAP is not necessarily time-cycled; it can be triggered by the patient. As with a pressure controlled, time-cycled mode, the duration of each phase (T(high), T(low)) as well as the
15 corresponding pressure levels (P(high), P(low)) can be adjusted independently from each other.

 Normally, the vagally-mediated Hering-Breuer (H-B) reflexes play a role in the maintenance of an adequate EELV. It is currently believed that, in mammals, phasic
20 stimulation of slowly adapting pulmonary stretch receptors located throughout the tracheobronchial tree and lungs, as would occur with each breath, modulates the frequency of breathing by inhibiting further inspiration during the inspiratory phase or causing prolongation of expiration during the expiratory phase; this is the Hering-Breuer reflex. Tonic stimulation of the same receptors, or other receptors, will also occur with changes in
25 residual lung volume (or Functional Residual Capacity (FRC)) to alter the timing of inspiration relative to expiration in a manner that acts to stabilize the residual lung volume. There may be other reflexes involved, but to date this is the most frequently described reflex. The mechanisms involved with regulating EELV comprise:

30 1. Braking of expiratory flow:

 It has been suggested that changes in a patient's upper airway resistance "brakes" expiration to EELV in order to promote an increase in EELV [Kosch, P.C.; Stark, A.R.; "Dynamic Maintenance of End-Expiratory Lung Volume in

Full-Term Infants"; J. Appl. Physiol.; Oct 1984; 57(4); pp 1126-33]. It has also been claimed that EELV is maintained by post-inspiratory EAdi (Electrical Activity of the diaphragm) [Mortola, J.P.; Fisher, J.T.; Smith, B.; Fox, G.; Weaks, S.; "Dynamics of Breathing in Infants"; J. Appl. Physiol.; May 1982; 52(5); pp 1209-15].

2. Tonic EAdi:

The article [Lopes, J.; Muller, N.L.; Bryan, M.H.; Bryan, A.C.; "Importance of Inspiratory Muscle Tone in Maintenance of FRC in the Newborn"; J. Appl. Physiol.; Oct 1981; 51(4); 830-4] points out the contribution of tonic EAdi (persistence of EAdi throughout the entire expiration) in the maintenance of EELV.

3. Respiratory timing:

A decrease in FRC reflexly increases T_e , which increases EELV by causing intrinsic PEEP. As indicated in the foregoing description, FRC is the Functional Residual Capacity, i.e. the volume of air in the lungs at the end of passive expiration. T_e is the neural expiratory time defined as the time between the end of neural inspiration and the beginning of the subsequent neural inspiration.

The expiratory braking mechanism is non-functional in intubated, mechanically ventilated infants, because the endotracheal tube maintains the infant's upper airways patent, albeit the presence of activation of the upper airway muscles. This interferes with the maintenance of EELV in intubated babies; the intubated babies must rely on the remaining two mechanisms ((2) Tonic EAdi (3) Respiratory timing) to maintain their EELV. Externally applied PEEP is almost always used in intubated babies with the intention of maintaining EELV; however, the level of PEEP to be applied is still determined in a more or less arbitrary fashion.

The presence of tonic EAdi in mechanically ventilated infants has been previously demonstrated and quantified [Emeriaud, G.; Beck, J.C.; Tucci, M.; Lacroix, J.; Sinderby, C.; "Diaphragm Electrical Activity during Expiration in Mechanically Ventilated Infants; 2003

ATS Abstract]. The diaphragm remains partially active during expiration, and is characterized by an initial period of post-inspiratory EAdi followed by tonic EAdi. The mean value of this tonic EAdi was 12-14% of the inspiratory Eadi. However, as can be seen in appended Figure 1, this end-expiratory tonic EAdi is quite variable.

5

SUMMARY OF THE INVENTION

More specifically, in accordance with the present invention, there is provided a
10 method of controlling positive pressure assist to a patient during expiration, comprising:
measuring a level of electrical activity of a patient's respiration-related muscle during
expiration; and, in response to the measured level of electrical activity, adjusting a level of
positive pressure assist to the patient during expiration in view of minimizing the level of
electrical activity of the patient's respiration-related muscle during expiration.

15

Also in accordance with the present invention, there is provided a device for
controlling positive pressure assist to a patient during expiration, comprising: means for
measuring a level of electrical activity of a patient's respiration-related muscle during
expiration; and means for, in response to the measured level of electrical activity, adjusting
20 a level of positive pressure assist to the patient during expiration in view of minimizing the
level of electrical activity of the patient's respiration-related muscle during expiration.

The present invention further relates to a device for controlling positive pressure
assist to a patient during expiration, comprising: a detector of a level of electrical activity of
25 a patient's respiration-related muscle during expiration; and a controller of a level of positive
pressure assist to the patient during expiration, the controller being supplied with the
measured level of electrical activity and controlling the level of positive pressure assist to
the patient during expiration in view of minimizing the level of electrical activity of the
patient's respiration-related muscle during expiration.

30

The foregoing and other objects, advantages and features of the present invention
will become more apparent upon reading of the following non-restrictive description of

illustrative embodiments thereof, given by way of example only with reference to the accompanying drawings.

5 BRIEF DESCRIPTION OF THE DRAWINGS

In the appended drawings:

Figure 1 is a graph showing the level of tonic EAdi of a mechanically ventilated infant
10 during expiration versus time;

Figure 2 is a flow chart illustrating the various operations of a non-restrictive
illustrative embodiment of the method according to the present invention, for controlling
positive pressure assist to a patient during expiration;

15 Figure 3 is a flow chart illustrating the various operations of a non-restrictive
illustrative embodiment of the method according to the present invention, for controlling
positive pressure assist to a patient during expiration; and

20 Figure 4 is a schematic block diagram of a non-restrictive illustrative embodiment of
a device according to the present invention, for conducting the method of controlling
positive pressure assist to the patient during expiration.

25 DETAILED DESCRIPTION OF THE ILLUSTRATIVE EMBODIMENT

The non-restrictive illustrative embodiment of the method and device according to
the present invention is concerned with control of positive pressure assist (positive
pressure/flow/volume) to a patient during expiration in relation to the level of electrical
30 activity of a patient's respiratory-related muscle. More specifically, the non-restrictive
illustrative embodiment of the method and device according to the present invention is
concerned with control of a ventilation feature selected from the group consisting of PEEP,

CPAP and BiPAP, applied to the patient's airway in relation to an EAdi level during expiration.

Although the non-restrictive illustrative embodiment of the method and device according to the present invention will be described in relation to control of a ventilation feature selected from the group consisting of PEEP, CPAP and BiPAP, these method and device can be applied to any other mode of mechanical ventilation that provides assist to a patient during expiration.

Also, although the preamble of this disclosure and the presently described non-restrictive illustrative embodiment of the method and device according to the present invention often make reference to babies and infants, it should be kept in mind that the method and device according to the invention can be applied as well to patients or subjects of any age, including adults.

The illustrative embodiment of the method and device of the present invention is based upon the principle that application of PEEP, CPAP or BiPAP will increase EELV, which in turn, via the tonic H-B reflex, will alter the tonic EAdi level. For example, when the level of PEEP, CPAP or BiPAP applied is too high, EELV will increase, and the tonic EAdi will be altered. One benefit of the illustrative embodiment of the method and device according to the present invention is that tonic EAdi can be maintained at a level that is not too "stressful" for the patient's diaphragm. Another benefit of the illustrative embodiment of the method and device according to the present invention is that expiratory lung collapse is avoided, in particular during the treatment of infants demonstrating lower than adequate EELV's.

Referring now to Figures 2 and 3, the non-restrictive illustrative embodiment of the method according to the present invention will now be described.

Operation 21

The method is started.

Operation 22

Since the hemodynamics of the patient, for example blood pressure, could be compromised if PEEP, CPAP or BiPAP during expiration is too high, an upper safety threshold for PEEP, CPAP or BiPAP is imposed by operation 22. This upper safety threshold for PEEP, CPAP or BiPAP during expiration can, for example, be clinically decided upon.

Therefore, operation 22 consists of comparing the current PEEP, CPAP or BiPAP during expiration with this upper safety threshold.

Operation 23

If the comparison performed by operation 22 indicates that the current PEEP, CPAP or BiPAP during expiration is equal to or higher than the safety upper threshold, the method is ended.

Operation 24

If the comparison performed by operation 22 indicates that the current PEEP, CPAP or BiPAP during expiration is lower than the imposed upper safety threshold, the PEEP, CPAP or BiPAP during expiration is increased, for example by a predetermined step.

The PEEP, CPAP or BiPAP can be increased once per patient's expiratory phase. Alternatively, the expiratory phase can be broken down into a plurality of segments and the PEEP, CPAP or BiPAP increased during each of these segments. The various segments can have the same duration or different durations.

Operation 25

A current EAdi level is measured during patient's expiration. For example, the current EAdi level during expiration can be measured by means of the double subtraction

technique as described in United States patent No. 5,671,752 granted to Sinderby et al., on September 30, 1997.

Obviously, the current EAdi level will be measured for each time period for which the PEEP, CPAP or BiPAP is increased, i.e. once per patient's expiratory phase or during each of the above-mentioned segments of the expiratory phase.

To confirm that the electrical activity measured during expiration is actually coming from the diaphragm, the following operations can be performed:

1. Detection of a negative correlation between EAdi signals at some point along a linear array of electrodes used to detect the electrical activity of the patient's diaphragm (see for example the above-mentioned United States patent No. 5,671,752); and
2. Sum of EAdi signals respectively above and below the diaphragm should be smaller than a difference between these signals.

Operation 26

This operation evaluates whether the current EAdi level measured during expiration is higher than the noise level. This evaluation constitutes an indication that the current measured EAdi level is not just noise but an actual EAdi signal level. Again, this operation will be performed during each time period for which the PEEP, CPAP or BiPAP is increased, i.e. once per patient's expiratory phase or during each of the above-mentioned segments of the expiratory phase.

For example, the EAdi level during expiration can be quantified as an absolute value above the noise level, or a percentage of inspiratory activity.

In this manner, operation 26 ensures that the stored lowest EAdi level during expiration is always higher than the noise level. This stored lowest EAdi level will be described hereinafter.

When the current EAdi level measured during expiration (operation 25) is lower than the noise level as determined by operation 26, the method returns to operation 25 to measure another value for the current EAdi level.

5 *Operation 27*

When the current EAdi level measured during expiration (operation 25) is higher than the noise level as determined by operation 26, this current EAdi level is compared to a previously stored (operation 28) lowest EAdi level during expiration to determine whether
10 this current EAdi level is lower than the previously stored lowest EAdi level. Again this comparison is made for each expiratory phase or during each of the above-mentioned segments of the expiratory phase, i.e. for each time period for which PEEP, CPAP or BiPAP is increased.

15 *Operation 28*

When comparison between the current EAdi level during expiration and the previously stored lowest EAdi level indicates that the current EAdi level measured during expiration is smaller than the stored lowest EAdi level during expiration, the current EAdi
20 level measured during expiration is stored as the new lowest EAdi level during expiration.

Operations 29 and 29'

The information from operation 27 that (a) the current EAdi level during expiration is
25 higher than the previously stored lowest EAdi level or (b) the current EAdi level during expiration is lower than the previously stored lowest EAdi level is communicated to operation 29 (Figure 2) or operation 29' (Figure 3) for each expiratory phase or for each of the above-mentioned segments of the expiratory phase, i.e. for each time period in which PEEP, CPAP or BiPAP is increased.

30
According to the illustrative embodiment of the method according to the present invention, when the EAdi level during expiration is higher than the noise level (operation 26) or when the EAdi level during expiration increases with time, PEEP, CPAP or BiPAP during

expiration will be increased until the EAdi during expiration decreases or ceases to increase.

Operation 29 (Figure 2)

5

Therefore, as illustrated in Figure 2, operation 29 is responsive to the information from operation 27 that (a) the current EAdi level during expiration is higher than the previously stored lowest EAdi level or (b) the current EAdi level during expiration is lower than the previously stored lowest EAdi level to determine whether the EAdi level during expiration decreases in response to increase of PEEP, CPAP or BiPAP during expiration. For example:

10

- when the EAdi level steadily decreases in response to increase of the PEEP, CPAP or BiPAP during expiration, operation 29 will indicate that the EAdi level decreases in response to increasing PEEP, CPAP or BiPAP during expiration; and
- when the EAdi level has not decreased for a few expiratory phases or a few segments of the expiratory phase, operation 29 will indicate that the EAdi level no longer decreases in response to increasing the PEEP, CPAP or BiPAP during inspiration.

15

20

When the decision of operation 29 is that the EAdi level during PEEP, CPAP or BiPAP during expiration decreases in response to increasing PEEP, CPAP or BiPAP, the method returns to operation 22. Otherwise, the method is ended (operation 23).

25

Operation 29' (Figure 3)

When the EAdi level during inspiration increases, as illustrated in Figure 3, operation 29' is responsive to the information from operation 27 that (a) the current EAdi level during expiration is higher than the previously stored lowest EAdi level during expiration or (b) the current EAdi level during expiration is lower than the previously stored lowest EAdi level during expiration to determine whether the EAdi level during expiration has ceased to increase in response to increase of the PEEP, CPAP or BiPAP during expiration. For example:

30

- when the EAdi level continues to increase in response to increase of the PEEP, CPAP or BiPAP during expiration, operation 29' will indicate that the EAdi level during expiration has not yet ceased to increase; and

5

- when the EAdi level has stopped to increase for a few expiratory phases or a few segments of the expiratory phase, operation 29' will indicate that the EAdi level during expiration has ceased to increase in response to increasing the PEEP, CPAP or BiPAP during inspiration.

10

When the decision of operation 29' is that the EAdi level during expiration has not ceased to increase, the method returns to operation 22. When the decision of operation 29' is that the EAdi level during expiration has ceased to increase, the method is ended (operation 23).

15

Since the patient's status is likely to change over time, verification of the PEEP, CPAP or BiPAP adjustment could also be included in the illustrative embodiment of the method according to the present invention. To verify that the PEEP, CPAP or BiPAP adjustment is appropriate over time, the PEEP, CPAP or BiPAP could be

20 intermittently/periodically reduced to monitor the effect on EAdi. Based on the response, the PEEP, CPAP or BiPAP can be adjusted.

25

The non-restrictive illustrative embodiment of a device according to the present invention for conducting the method of Figures 2 and 3 will now be described with reference

25 to Figure 4.

30

This non-restrictive illustrative embodiment of the device according to the present invention comprise a detector 44 of the current EAdi level during inspiration and a controller 49 of the positive pressure assist to a patient during expiration.

30

In the controller 49, a comparator 41 compares the current PEEP, CPAP or BiPAP during expiration with the upper safety threshold.

When the comparison performed by the comparator 41 indicates that the current PEEP, CPAP or BiPAP during expiration is equal to or higher than the safety upper threshold, the method is ended by a method ending unit 42.

5 If the comparison performed by the comparator 41 indicates that the current PEEP, CPAP or BiPAP during expiration is lower than the imposed upper safety threshold, a unit 43 increases the PEEP, CPAP or BiPAP during expiration, for example by a predetermined step. Again, the PEEP, CPAP or BiPAP can be increased for each expiratory phase or for each of the above-mentioned segments of the expiratory phase.

10 A detector 44 measures a current EAdi level during patient's expiration. As indicated in the foregoing description, the current EAdi level during expiration can be measured by means of the double subtraction technique as described in United States patent No. 5,671,752 granted to Sinderby et al., on September 30, 1997, for each time period for which
15 the PEEP, CPAP or BiPAP is increased, i.e. once per patient's expiratory phase or during each of the above-mentioned segments of the expiratory phase.

A comparator 45 evaluates whether the current EAdi level measured during expiration is higher than the noise level. This evaluation constitutes an indication that the
20 current measured EAdi level is not just noise but an actual EAdi signal level. Again, this operation will be performed during each time period for which the PEEP, CPAP or BiPAP is increased, i.e. once per patient's expiratory phase or during each of the above-mentioned segments of the expiratory phase.

25 The comparison performed by the comparator 45 ensures that the lowest EAdi level during expiration memorized within the store 47 is always higher than the noise level.

When the current EAdi level measured during expiration by the detector 44 is lower than the noise level as determined by the comparator 45, the detector 44 conducts a new
30 measurement of the current EAdi level.

When the current EAdi level measured during expiration by the detector 44 is higher than the noise level as determined by the comparator 45, another comparator 46 compares

the current EAdi level to a lowest EAdi level during expiration previously stored in store 47 to determine whether this current EAdi level is lower than the previously stored lowest EAdi level. Again this comparison is made for each expiratory phase or during each of the above-mentioned segments of the expiratory phase, i.e. for each time period for which PEEP, CPAP or BiPAP is increased.

When comparison between the current EAdi level during expiration and the previously stored lowest EAdi level indicates that the current EAdi level measured during expiration is lower than the stored lowest EAdi level during expiration, the store 37 memorizes the current EAdi level during expiration as the new lowest EAdi level during expiration.

The information from comparator 46 that (a) the current EAdi level during expiration is higher than the previously stored lowest EAdi level or (b) the current EAdi level during expiration is lower than the previously stored lowest EAdi level is communicated to a sub-controller 48 for each expiratory phase or for each of the above-mentioned segments of the expiratory phase, i.e. for each time period in which the PEEP, CPAP or BiPAP is increased.

For example, when the EAdi level steadily decreases in response to increase of the PEEP, CPAP or BiPAP during expiration, the sub-controller 48 will detect that the EAdi level still decreases and will request the comparator 41 and unit 43 to increase the PEEP, CPAP or BiPAP. Also, when the EAdi level has not decreased for a few expiratory phases or a few segments of the expiratory phase, the sub-controller 48 will detect that the EAdi level during expiration no longer decreases and will request the unit 42 to end the method.

According to another alternative, when the EAdi level during inspiration increases, the sub-controller 48 is responsive to the information from the comparator 46 that (a) the current EAdi level during expiration is higher than the previously stored lowest EAdi level or (b) the current EAdi level during expiration is lower than the previously stored lowest EAdi level to determine whether the EAdi level during expiration has ceased to increase in response to increase of the PEEP, CPAP or BiPAP during expiration. For example:

- when the EAdi level continues to increase in response to increase of the PEEP, CPAP or BiPAP during expiration, the sub-controller 48 will detect that the EAdi level has not ceased to decrease and will request the comparator 41 and unit 43 to increase the PEEP, CPAP or BiPAP; and

5

- when the EAdi level has stopped to increase for a few expiratory phases or a few segments of the expiratory phase, the sub-controller 48 will detect that the EAdi level has ceased to increase in response to increasing the PEEP, CPAP or BiPAP during inspiration and will request the unit 42 to end the method.

10

Although the present invention has been described hereinabove in connection with illustrative embodiments thereof, these illustrative embodiments can be modified at will, within the scope of the appended claims without departing from the spirit and nature of the subject invention.
